JVM	Java Virtual Machine
NFA	Nondeterministic finite automaton
TDD	Test Driven Development

1 Introduction

Compilers are programs that transform a source language into a lower target language. A source program and a compiler serve as input. Afterwards, the execution takes place on a machine. On the other hand, an interpreter translates command by command and executes them directly on the machine. However, a compiler is faster because no interpreter has to be active at runtime and it can be optimized better but it is more difficult to implement. An example of a compiled language is C++¹. Another example of an interpreted language is Python².

This paper deals with the implementation of a platform-independent compiler for a language called *E. ANother Tool for Language Recognition* (ANTLR), an object-oriented parser generator, is used for this purpose. Of course, there are already several compilers like C++ or Fortran³. However, there are several reasons why new compilers also make sense. On the one hand, a new way of thinking is to be tried out. Haskell⁴ investigated e.g. laziness in the language or BASIC⁵ wanted to make learning easier for programmers. Here, conventional language properties are to be removed as far as possible until a Turing machine-like language remains whereby the compiler is kept small. Furthermore, the language concept is kept very simple so that a lot can be described with as little expression as possible without limiting the universal readiness for use. Finally, concepts for application-oriented languages will be demonstrated. For example, these include loops and conditions. The goal is to explicitly promote structural thinking. During the implementation, special attention is paid to how trees are traversed efficiently so that the code can be generated optimally.

The compiler is designed according to various quality criteria. It must deliver correct results and react to any operating errors with a well-defined state. Furthermore there should be an understandable user documentation and the source code should be readable. Ultimately, another goal is portability on multiple systems. Software tests are used to detect and localize errors and contribute to quality assurance. Specifically, module tests and integration tests are used. Thus modules are also examined together.

The explanation of the compiler is based on the respective compiler phases which are subdivided into an analysis and synthesis (see chapter 2 on page 8). With regard to analysis, this concerns lexical, syntax and context analysis. The code generation is about generating assembler-like instructions. Furthermore, the module and integration tests are explained in chapter 3 on page 55 to investigate the quality of the compiler.

2 Compiler Phases

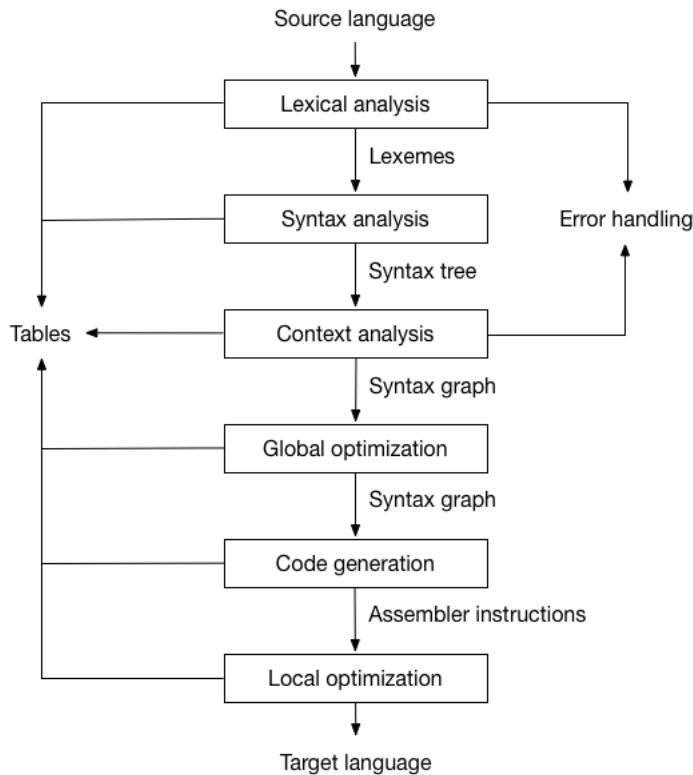

Figure 1: Compiler phases

The figure 1 shows the compilation process which starts with the input of a *source program*. The program must be written in *E*.

The lexical, syntax and context analysis are a part of the analysis phase. This is primarily about the properties of the source program. The *lexical analysis* is about recognizing words (see chapter 2.1 on page 12). The *syntax analysis* then builds a logical structure of the lexemes (see chapter 2.2 on page 18). The *context analysis*, on the other hand, includes e.g. a type test. The result is then a syntax graph. During these phases, *errors* are always handled. Accordingly, the system checks, for example, whether a variable was used before the definition. The *global optimization* makes an optimization on the source text. Thus e.g. isomorphies are summarized in the code.

The *code generation* represents the synthesis. The structure of the source program already exists there. The synthesis consists of three components:

- **Allocation:** The available components like a Graphics Processing Unit (GPU) are selected.
- **Binding:** The specific functions are mapped to the components.
- **Control flow:** The chronological sequence of the commands is displayed.

It generates assembler instructions and is therefore dependent on the respective instruction set of the processor. This refers, for example, to the allocation of registers which is generally NP complete [BDR06], i.e. there are only runtime-intensive algorithms for an exact solution. Moreover, hashtables are used for quick access to identifiers or strings. *Local optimization* is again based on basic blocks. These start with the entry into a control flow and end with the exit. However, they do not include jumps. More about this topic can be found in chapter 2.4 on page 47. The main goal here is to rearrange commands. The bytecode for the source language E then results.

Altogether, there is a difference between runtime and compile time which is shown in the tombstone diagram⁶ 2:

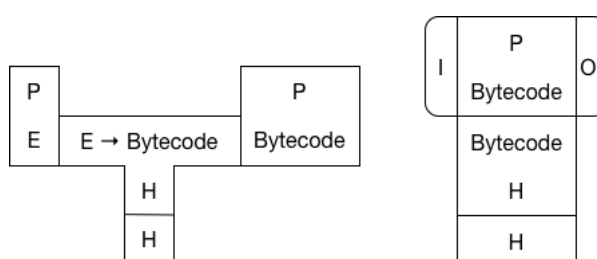

Figure 2: Compile time and runtime

The compile time refers to the compiler phases (see figure 1 on page 8). The language E is transformed by a host (H) to bytecode. The execution also happens there. The bytecode can then be interpreted at runtime where it is located in the Java Virtual Machine (JVM). Therefore it is also possible to generate code for different central processing units (CPU) like PowerPC or x86. However, the code can also be translated on a different architecture and then executed elsewhere. Accordingly, retargeting and rehosting are supported.

In the following, the respective components of the compiler will be explained. The following folder structure regarding the architecture is used as help:

The folder *grammar* contains the defined grammar with the parser and lexer rules. In the folder *lib* you can also find the used libraries for ANTLR and Jasmin (see chapter 2.4 on page 47). In summary, a Maven⁷ project is used where these are listed as dependencies in the *pom.xml* (see appendix on page 63). The actual source files are divided into the folders *compiler* and *parser*. The *compiler* folder contains the defined logic for traversing the tree with code generation (see chapter 2.3 on page 27) and the start method for starting a file such as *main.e* written in the language *E*. The folder *e* also contains the standard library of the language that can be imported. The *exception* package contains error classes for incorrect use of the described constructs regarding the context analysis of language *E*. For example, a message is generated when a variable is used although it has not yet been declared. Another example would be that an error message appears when a function is defined twice or if a data type is not compatible with an operation. In the *parser* folder there is a lexer and a parser to make analyses. The recognized tokens can also be found there. The unit and integrations tests can be found in the *test* folder (see chapter 3 on page 55). The respective tests also read test files from the *resources* folder if the corresponding source code is relatively long. Among other things, this refers to the tests for functions, branches, loops and operators. The respective compilates are created in the *target* folder.

Note: For a better overview, several comments have been removed in the codes. However, these are visible in the *E Compiler*⁸ as a Maven project. The current description of the installation of the compiler is shown in the respective *README.md*.

2.1 Lexical analysis

Generally speaking, lexical analysis creates lexemes from source code. The scanner is responsible for recognizing lexemes. The screener, on the other hand, performs actions after recognition. This includes e.g. removing comments. Each lexeme consists of one or more characters. These include, for example, printable characters such as letters or numbers but also control characters such as tab stops. The encoding of the characters is limited to American Standard Code for Information Interchange (ASCII). The code can be found in the appendix on page 66.

The lexical analysis is done with finite automata, i.e. the lexemes are described by regular expressions.

Definition 1 (Deterministic finite automaton):

A deterministic finite automaton (DFA) is a 5-tuple, $(Q, \Sigma, \delta, q_0, F)$, consisting of a finite set of states Q , a finite set of input symbols called the alphabet Σ , a transition function $\delta : Q \times \Sigma \rightarrow Q$, an initial or start state $q_0 \in Q$ and a set of accept states $F \subseteq Q$.

Definition 2 (Nondeterministic finite automaton):

A nondeterministic finite automaton (NFA) is represented by a 5-tuple, $(Q, \Sigma, \Delta, q_0, F)$, consisting of a finite set of states Q , a finite set of input symbols Σ , a transition relation $\Delta : Q \times \Sigma \rightarrow P(Q)$, an initial state $q_0 \in Q$ and a set of states F distinguished as accepting or final states $F \subseteq Q$. Here, $P(Q)$ denotes the power set of Q .

Definition 3 (Regular expression):

Be Σ an alphabet. \emptyset and ϵ are regular expressions, a is a regular expression of Σ for all $a \in \Sigma$. If R_1 and R_2 are regular expressions, then also $R_1 \cup R_2$, $R_1 \circ R_2$ and R_1^* are regular expressions.

Definition 4 (Regular language):

A regular language is a language that can be expressed with a regular expression or a deterministic or non-deterministic finite automata or state machine.

Definition 5 (Grammar):

A grammar is a 4-tuple, (N, Σ, P, S) , consisting of a finite set N of nonterminal symbols, a finite set Σ of terminal symbols, a finite set P of production rules with $(\Sigma \cup N)^* N (\Sigma \cup N)^* \rightarrow (\Sigma \cup N)^*$ and a distinguished symbol $S \in N$ that is the start symbol.

Type-3 grammars generate regular languages and have a single non-terminal on the left-hand side as well as a right-hand side consisting of a single terminal or single terminal followed by a single non-terminal. The productions have the form $X \rightarrow a$ or $X \rightarrow aY$ where $X, Y \in N$ and $a \in \Sigma$. Moreover, the rule $S \rightarrow \epsilon$ is allowed if S does not appear on the right side of any rule.

For the language E there are different lexemes which can be distinguished as follows in code 1:

```

1 // -----
2 // Here are the built-in functions of the language E where an access is possible even
3 // without imports.
4
5 BUILTINFUNCTION      : 'toInt'
6                       | 'toFloat'
7                       | 'toString'
8                       | 'append'
9                       | 'length'
10                      ;
11
12 // -----
13 // Represents the two truth values of logic (true, false).
14
15 BOOL                 : 'true'
16                       | 'false'
17                      ;
18
19 // -----
20 // Refers to integers
21
22 INTEGER              : (DIGIT)+
23                      ;
24
25 // -----
26 // Refers to floating point numbers
27
28 FLOAT                : INTEGER DOT INTEGER
29                      | DOT INTEGER
30                      ;
31
32 // -----
33 // Any number of characters, but as little as possible that the rule is still
34 // fulfilled
35
36 STRING               : QMARK .*? QMARK
37                      ;
38
39 // -----
40 // Identifiers
41
42 IDENTIFIER           : LETTER(LETTER | DIGIT)*
43                      ;
44
45 // -----
46 // (Multi)line comments (but as little as possible that the rule is still fulfilled)
47
48 COMMENT              : ('/' ~[\r\n]* '\r'? '\n' | '/*' .*? '*/' | '/*'
49                      .*? '*/') -> skip
50                      ;
51
52 // -----
53 // Ignore control characters (the screener removes these)
54
55 WHITESPACE           : [ \t\n\r]+ -> skip
56                      ;

106 fragment DIGIT   : [0-9]
107                  ;
```

Code 1: Lexer rules of grammar E

Conventionally, the rules for the Lexer are written in capital letters. A distinction is also made between meta and object characters. Thus, for example `+` is a metacharacter which states that an integer must consist of at least one digit. However, `toInt` is an object character that defines a built-in function. Repeating tokens such as brackets

{ etc. are stored separately. The different comments are removed by the screener. In addition, there are different data types:

- Booleans like `true`
- Integers like `5`
- Floating point numbers like `0.5` or `.5`
- Strings like `"world"`
- Arrays
- Structures and the corresponding objects

The concrete composition of the arrays and structures can be seen in chapter 2.2 on page 18. A data type can be primitive or an object associated with references whereby they consist of fragments such as digits. A fragment will never be counted as a token, it only serves to simplify a grammar and makes the grammar more readable as well as easier to maintain. A special feature of the strings is that they may consist of any number of characters but only so few that the rule is still fulfilled. This ensures that strings may not apply beyond quotation marks. The same principle applies to comments. The keywords are still reserved. Furthermore, the layout is not ignored. For this reason, no lookahead is required for the automaton. Finally, the performance is increased. In addition, the compiler also knows the position in the source code so that more concrete error messages can be output (see chapter 2.3 on page 27). The generation of the automaton or tables for the lexemes is shown in the following figure 3:

Figure 3: Workflow of the lexical analysis

The workflow of the scanner is explained below using the example `R = LETTER(LETTER | DIGIT)*` (see figure 4 on page 16). First of all, the graph transformation takes place on the basis of rules. These come from the proof of the equivalence of finite automata and regular expressions [Vis13]. The rules for graph transformation can be found in the appendix on the page 68.

Figure 4: Graph transformation on a regular expression

Accordingly, a NFA with epsilon transitions is formed. The epsilon transitions must then be removed and the powerset construction applied⁹. First, states are marked for this purpose:

⁹Powerset construction, <http://www.cs.nuim.ie/~jpower/Courses/Previous/parsing/node9.html>

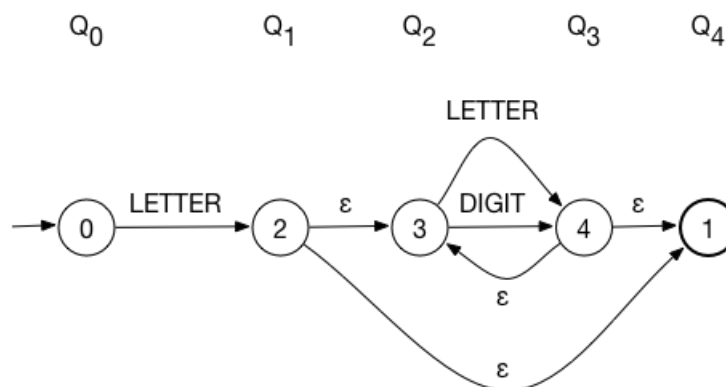

Figure 5: Powerset construction at a NFA

According to figure 5, the states $Q_0 = \{0\}$, $Q_1 = \{2, 3, 1\}$, $Q_2 = \{3\}$, $Q_3 = \{4, 3, 1\}$ are reached depending on the epsilon transitions. Q_4 is dropped here because there is nothing to read. Because the DFA states consist of sets of NFA states, an n-state NFA may be converted to a DFA with at most 2^n states. A converted DFA has exactly 2^n states, so giving an exponential time complexity. However, this runtime can be neglected since it is before the compile time.

When minimizing, the same states are combined or unattainable states are removed. Two states are equal if they have the same transitions. In concrete terms, equivalence classes are formed by applying the Table Filling method¹⁰. The resulting minimum DFA is shown in the figure 6 below.

Figure 6: DFA after minimization

Afterwards, the DFA is mapped to a table 1:

Table 1: Realization of a DFA in a table

	LETTER	DIGIT
0	2	
2	2	2

Valid words or identifiers are thus e.g. “_test” or “t3st”. Finally, all DFAs are combined for the respective lexemes. Alternatively, GOTO or WHILE programs¹¹ can be used

¹⁰Table Filling method, <http://pages.cs.wisc.edu/~shuchi/courses/520-S08/handouts/Lec7.pdf>

¹¹GOTO and WHILE programs, <https://www.informatik.hu-berlin.de/de/forschung/gebiete/algorithmenII/Lehre/ws11/einftheo/skript/einftheo-goto.pdf>

instead of tables to show computability. The corresponding code can be found in the appendix on the page 69.

2.2 Syntax analysis

The syntax analysis generates an abstract syntax tree (AST) from lexeme sequences. The basis for this is the extended Backhus-Naur Form (EBNF) which is a metalanguage for the description of context-free or Type-2 grammars (CFGs). Type-2 grammars generate context-free languages. The productions must be in the form $X \rightarrow a$ where $X \in N$ and $a \in (\Sigma \cup N)^*$. These languages generated by these grammars are recognized by a non-deterministic pushdown automaton.

Definition 6 (BNF):

The BNF is a formal notation for encoding grammars intended for human consumption. Every rule in BNF has the structure `name ::= expansion` where `::=` means “may expand into” and “may be replaced with”. The `name` stands for a non-terminal symbol. Every name in BNF is surrounded by angle brackets, `<>` whether it appears on the left- or right-hand side of the rule. An expansion is an expression containing terminal and non-terminal symbols, joined together by sequencing and choice. A terminal symbol is a literal or a class of literals.

Definition 7 (EBNF):

The EBNF is a collection of extensions to BNF but not all of these are strictly a superset, as some change the rule-definition relation `::=` to `=`, while others remove the angled brackets from non-terminals. Additional operations are options (`<term> ::= ["-"] <factor>`), repetitions (`<args> ::= <arg> ", " <arg>)` and groupings (`<expr> ::= <term> ("+" | "-") <expr>`).

In contrast to the conventional BNF, the EBNF therefore requires fewer constructs to describe CFGs. For example, options `[]` or repetitions can be used directly to present constructs more compactly instead of using recursions [Chu09].

Essentially, a derivation tree is generated by the parser during the analysis which also states how it was derived. In this way, a differentiation was also made to a recognizer. As already mentioned in the introduction, ANTLR is used as a parser generator. ANTLR uses the top-down approach instead of a bottom-up parsing, i.e. a recursive descent parser is used. The input is processed from left to right by calculating a left derivation. This means that an attempt is made to create the desired word from a start symbol. Note that there are several language classes of CFGs that can be parsed deterministically whereby ANTLR handling $LL(k)$ grammars. The k stands for the respective lookaheads that can be made. If there are many lookaheads, there are fewer

conflicts but more states. At E $k = 1$ was set. The language classes are listed in the appendix on page 71.

The parser is divided into three parts, a configuration, execution and actions which are explained in the following table 2:

Table 2: Functionality of the recursive descent parser

Part	Description
Configuration	$\alpha.w$
Execution	$s.w_0 \vdash^* \epsilon.\epsilon$
Actions	$match: a\alpha.aw \vdash_a \alpha.w$ $expand: A\alpha.w \vdash_p \beta\alpha.w$, where $p : A \rightarrow \beta \in P$

Here, α corresponds to the hypothesis N^* and w is the unread input. With regard to the execution, the start and end configuration are visible. The *match* function is called when a terminal is derived. With *expand*, on the other hand, a rule is generally applied. It is obvious that *expand* as oracle advises the next application of a rule in doubt. If there is an error or a match, backtracking must be used and there is an exponential runtime. In order to obtain a linear runtime, special care was taken to define a deterministic CFG for the language E .

Definition 8 (Ambiguous grammar):

A grammar means ambiguous if $w \in \Sigma^*$ so that several derivation trees or left and right derivations exist.

In general, it is undecidable whether a grammar is ambiguous which can be shown by a reduction of PKP to this problem [HM11, p.461-462]. In addition, a left factorization $[A \rightarrow \alpha\beta_1\gamma, A \rightarrow \alpha\beta_2\gamma] \rightarrow [A \rightarrow \alpha B\gamma, B \rightarrow \beta_1, B \rightarrow \beta_2]$ ($\alpha \neq \epsilon$) was used for the recursive descent regarding the processing. Thus, for example, precedents in arithmetic or logical operations are taken into account. In the following, the CFG for the language E in code 2 is presented and explained:

```

1 // Start rule
2 // It is evaluated from left to right.
3 // A program consists of statements, functions or structures.
4
5 program                                : inclst+=includes* noMains+=noMain* command+ EOF
6                                     ;
7
8 // -----
9 // Allows the import of different modules for e.g. mathematical calculations.
10
11 includes                              : 'use' OPAREN (modst+=module)+ (COMMA (modst+=module))*
12                                     CPAREN
13                                     ;
14
15 // -----
16 // A namespace can consist of several modules that are separated from each other by

```

2 Compiler Phases

```
17 // dots.
18

Code 2: Parser rules of grammar E

It should be mentioned that first as well as follow sets $F_i(N)$ and $F_o(N)$ were created to promote a left factorization which is why double entries are not allowed. The

first set includes the start of a derivative of the variable in the grammar and the follow set the subsequent derivatives of the symbols that are possible or where the variable can be used. It applies, for example, $F_i(\text{variableDeclaration}) = \{\text{var}\}$ and $F_o(\text{variableDeclaration}) = \{ '=', ';;' \}$. Conventionally, the parser rules consist only of minuscules. The start symbol of the grammar is **program**. The evaluation takes place from left to right. In the grammar different constructs of the language E are listed. A program consists of commands, i.e. statements, structures and functions. EOF means in this context that it definitely parses to the end of the file, even if errors occur before it. This results in a total output of all errors made. Statements must be in the main program or in blocks of functions or structures. They can also contain expressions or appear again in statements. An example is **if-else**. It may contain expressions, but may appear in a loop. Functions as well as structures are outside in this context. They are separated from the main program. This means that definitions and declarations can also be made after use. There are commands such as:

- Imports like `use(e.io.reader)`
- Import calls like `String r = reader.read(): String;`
- Macro Instructions like `#define noMain`
- Outputs like `print("world");`
- Variable declarations or assignments like `int a;` as well as `float a = 5.3;`
- Function definitions like `void foo(int a, int b) { print(a*b); }`
- Function calls like `foo(7, 8);`
- Branches like `if (x) { a = 5; } else { a = 7; }`
- Loops like `int i = 0; while (i < 3) { println(i); i = i + 1; }`
- Built-in functions like `toInt(3.7);`
- Inline assembler like `invoke "static" "java/lang/System/nanoTime"() "J";`
- Structures like `struct Point { int x; int y; }`
- Struct initializations like `Point p = new Point(1, 2);`
- Arrays like `int[] a = new int[5];`
- Arithmetic operators like `a + b`
- Shift operators like `a » b`
- Relational operators like `a <= b`
- Logical operators like `a && b`

The use of while loops make E Turing complete [Zei18]. For this reason, it can be used to simulate any Turing machine. This means that this system is able to recognize or decide other data-manipulation rule sets. It is also possible, for example, to specify expressions such as multiplication or a number directly within the output. In order to increase readability, various labels such as `arg=expression` has been assigned to `print`. This makes it easier to access the respective expression such as a number or string by `arg` via the context within the visitor pattern during traversing (see chapter 2.3 on page 27). The parser rules therefore directly access the lexer rules. Labels were also awarded for a rule that allows several derivatives. An example of this is the subtraction or addition that has the label `#SubtractionAdditionExpression`. Thus this rule can later be addressed directly by `visitSubtractionAdditionExpression` during traversing and also has its own context `SubtractionAdditionExpressionContext`. The same applies analogously to the other commands. Labels must not comply with the rules or be duplicated. The respective precedents are guaranteed by the order in which ANTLR4 follows sequentially. Different expressions can also be used in blocks such as branches. This allows statements to exist that do not have a semicolon at the end. In addition, symbols such as `+=` ensure that parameters can be counted which is particularly important for functions and later type analysis. Basically, functions are divided into call and definition by `functionDefinition` as well as `functionCall`. Functions are defined in the header and there does not have to be a declaration of variables. Furthermore, they can also be overloaded, i.e. the same name with different but arbitrarily long parameters is possible. The same principle applies to self-defined types such as structures.

The top-down parser uses a (simplified) abstract syntax to create the commands shown in the figure 7:

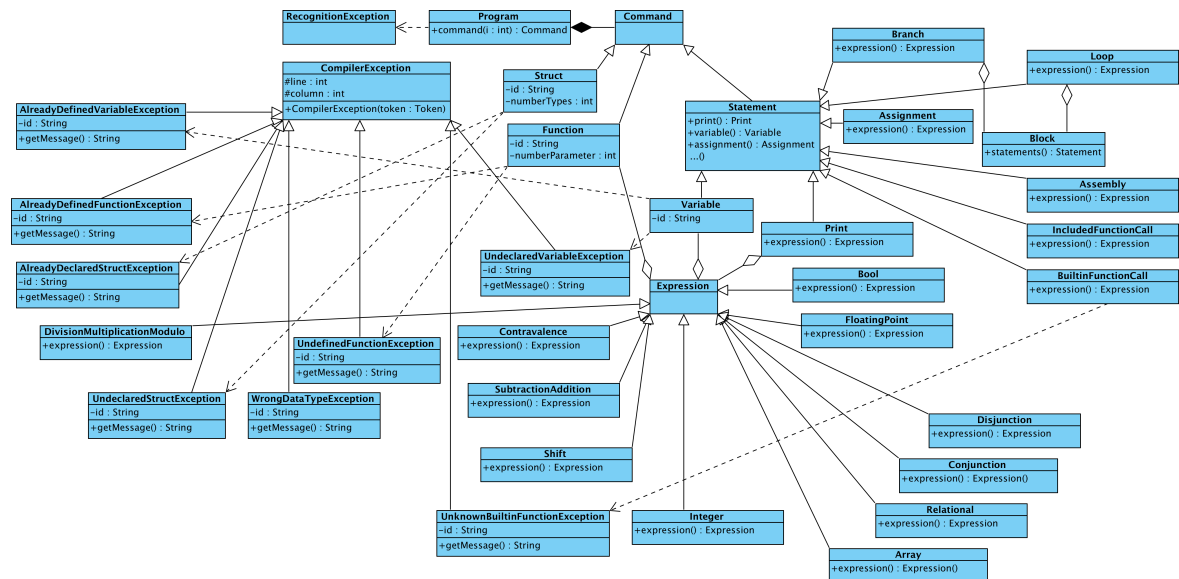

Figure 7: Abstract syntax

The AST is therefore described as an object structure by the abstract syntax. For simplicity, further edge markers, constructors and query functions have been omitted. Among other things, it can be recognized that commands cannot exist without a program. Furthermore, variables or functions can be used in expressions that are evaluated. Expressions can also be used, for example, in branches. Certain associated error classes ensure that users of language E are notified of incorrect operation. The corresponding instructions for creation are in this document (simplified) parser and can be found in the appendix on page 72. There is a procedure for each parser rule where the next lexeme l is treated. Error handling is also performed during parsing. For example, the character `@` does not belong to any expression and in this case a `RecognitionException` would be thrown because this object character is not known. If a procedure is called, then $l \in F_i$ applies before. Then $l \in F_o$ is valid.

In the following, an AST is generated from the program code `print(3+2*4)` as an example:

$$\begin{aligned} &program \vdash command; \\ &\quad \vdash statement; \\ &\quad \vdash print; \\ &\quad \vdash print(expression); \\ &\quad \vdash print(expression + expression); \\ &\quad \vdash print(3 + expression); \\ &\quad \vdash print(3 + expression * expression); \\ &\quad \vdash print(3 + 2 * expression); \\ &\quad \vdash print(3 + 2 * 4); \end{aligned}$$

Thus, a derivation tree could be successfully generated whereby the precedents are controlled by the ranking order. This also means that an ambiguous grammar must be checked. The corresponding AST is shown in figure 8 on page 27:

Figure 8: Abstract syntax tree

Due to the recursive definitions, a tree with theoretically infinite depth is created and can be traversed post-order to generate the instructions which will be explained in the next chapter.

2.3 Context analysis

In general, an AST is marked with attributes during context analysis. These stand for cross-references with regard to definitions or usage. The AST then becomes an abstract syntax graph (ASG) which can also contain cycles due to recursions. The general steps are as follows:

1. **Declaration analysis:** Checks, for example, whether a variable was declared before use.
2. **Type analysis:** Checks, for example, whether formal and current parameters match for functions.

Thus, all rules that cannot be covered with a scanner (see chapter 2.1 on page 12) or parser must be checked. In the context, this includes both static (variable must have been defined) and dynamic conditions (a variable must be in the index area).

To describe the context conditions, a syntax-directed transduction is used instead of a two-level grammar, i.e. recursive functions are used on the AST.

On the described object structure from chapter 2.2 on page 18 a general visitor can be defined who traverses the tree from which can be inherited later. A visit function is

used to visit all connected elements. From this general visitor different visitors can be derived who define different operations on the AST. An excerpt of this visitor can be seen in the following code 3:

```
public class EVisitor extends EBaseVisitor<String> {
2   /** A list with all already defined functions */
   private final FunctionPrototypeList functions;

Code 3: Implementation of `EVisitor.java`

Accordingly, a semantic analysis can be realized in a visitor. Thus, new operations can be easily added by defining new visitors and related operations can be centrally managed in the visitor. The elements of the tree are visited which e.g. extends the symbol table information of variables. Expressions can also be checked to see if they are well typed. A visitor is used who also takes over the synthesis at the same time which will be explained in the next chapter.

To demonstrate how the tree is traversed, the example shall serve in the form of the figure 8 on page 27. The tree is traversed post-order due to the later code generation. Thus, the children are treated first before the parents are processed. Finally, the terminals are determined with `getText`. In the example, `3, 2, 4, *, +` would be determined. As already mentioned, there is a corresponding method for each desired operation. Besides the methods of the base class for `program` and `statement`, `visitPrint` is called with the corresponding context. Then, `visit` is called with an expression as argument (here the addition) for producing the respective code. Now, `visitChildren` is called in `visitSubtractionAdditionExpression` where the context is passed. The method `visitChildren` visits the children of a node and returns a user-defined result of the specific operation. In contrast to this, the method `visit` visits a parse tree and return a user-defined result of the operation. On the one hand, `visitIntegerExpression` is called where the first number is determined. On the other hand, the right child is a multiplication where `visitDivisionMultiplicationModuloExpression` (analogous to addition) is called. Then, the further numbers are determined. Afterwards, the parents are determined, namely `*` and `+`. The corresponding aggregation of the string is explained in chapter 2.4 on page 47. Data types have also been implemented in the

compiler. So only the integers and floating point numbers work in the arithmetic operations which is queried via conditions. Otherwise an exception is thrown. In order to manage the data types, a stack is used as data structure which is visible in code 4:

```

1  public class DataTypeStack {
    /** A linked list of types */
3  private final Deque<TypeInformation> typesStack;

5  /** Maximum stack size for variables and so on */
    private int maxStackSize;

7
    DataTypeStack() {
9        typesStack = new LinkedList<>();
        maxStackSize = 0;
11    }

13    public final void push(TypeInformation type) {
        if (type.getDataType() != DataType.VOID) {
15        typesStack.push(type);
        }
17        if (typesStack.size() > maxStackSize) {
            ++maxStackSize;
19        }
        }

21
23    public final TypeInformation pop() {
        return typesStack.pop();
    }

25
27    public final TypeInformation peek() {
        return typesStack.peek();
    }

29
31    public final int getMaxStackSize() {
        return maxStackSize + 1;
    }

33 }

```

Code 4: Implementation of `DataTypeStack.java`

The stack manages overall type information whereby this class is visible in code 5:

```

1  public class TypeInformation {
    /** Id (the position in the symbol table regarding variables) */
3  private int id;

5  /** Type of the construct (function, variable, ...) */
    private final DataType dataType;

```

```

7      /** Address of a type (structure) regarding references */
9      private int address;
10
11      ...
12
13      public final String getJvmType() {
14          if (dataType != DataType.OBJREF) {
15              return dataType.getJvmType();
16          } else {
17              return Integer.toString(address);
18          }
19      }
20
21      public final boolean isArray() {
22          switch (dataType) {
23              case IARRAY:
24              case FARRAY:
25              case SARRAY:
26                  return true;
27              default:
28                  return false;
29          }
30      }
31  }

```

Code 5: Implementation of `TypeInformation.java`

This class stores a type and also an address if, for example, a reference to a structure exists. Accordingly, a variable can later be assigned to a structure. A distinction is made between objects and primitive data types that are visible in code 6:

```

1  public enum DataType {
2      /** A specific type regarding the JVM and E. */
3      BOOL("bool", "Z"),
4      INT("int", "I"),
5      IARRAY("int []", "[I"),
6      FLOAT("float", "F"),
7      FARRAY("float []", "[F"),
8      STRING("String", "Ljava/lang/String;"),
9      SARRAY("String []", "[Ljava/lang/String;"),
10     VOID("void", "V"),
11     OBJREF("", "");
12
13     /** Type in E */
14     private final String type;
15
16     /** Type in the JVM */
17     private final String jvmType;
18
19     ...

```

```
19     public static DataType getType(final String type) {  
20         switch (type) {  
21             case "bool":  
22                 return BOOL;  
23             case "int":  
24                 return INT;  
25             case "int []":  
26                 return IARRAY;  
27             ...  
28             default:  
29                 return OBJREF;  
30         }  
31     }  
32     ...  
33 }
```

Code 6: Implementation of `DataType.java`

For example, if an integer is called, the corresponding data type `INT` is pushed onto the stack. With an addition, this procedure is repeated. The addition can then pop these two data types from the stack and make decisions according to the code generation. The data type for the result is then pushed onto the stack again so that `print` uses the correct data type for the output. The individual abbreviations stand for the data type in binary code and are explained in the next chapter.

As already mentioned, the symbol table can also be extended in the context of variables. So in case of a variable declaration like `int a` the method `visitVariableDeclaration` is called and the position as well as the type is saved to the identifier. If a reference exists, the corresponding address for the object is also saved. If the variable already exists for an assignment, the position is determined and the corresponding value is saved. Otherwise, the procedure is analogous to the declaration. Later, the value of the variable can be retrieved if `visitVariableExpression` is called during traversing. Such expressions can also occur in branches or loops with blocks where the evaluation then takes place in `visitBranch` or `visitLoop`. Since labels must be unique, a counter `branchCounter` respectively `loopCounter` is incremented accordingly.

The same principle is not applied to functions because a function may be called if the definition is further down in the program. For this reason, functions have their own visitor which first collects the signatures (name and parameter types of the functions) and pass them to the visitor from code 3 on page 28. This also ensures total visibility. As already mentioned, a function can also have a body of any length. So that local variables can also be used, there are different local and one global scope. For example, the corresponding realization is visible in the method `visitFunctionPrototypes` where a

new reference to an own symbol table is made. The visitor for functions is shown in code 7:

```
1 public class FunctionDefinitionVisitor {
2     public static FunctionPrototypeList findFunctionPrototypes(
3         final ParseTree tree) {
4         // Remember all prototypes of defined functions
5         final FunctionPrototypeList definedFunctionPrototypes =
6             new FunctionPrototypeList();
7         // Notice the built-in functions
8         setBuiltInFunctionDefinitions(definedFunctionPrototypes);
9         // An anonymous class
10        new EBaseVisitor<Void>() {
11            @Override
12            public Void visitFunctionDefinition(FunctionDefinitionContext
13                ctx) {
14                // Get return type
15                final DataType returnType = DataType.getType(ctx.type
16                    .getText());
17                // Get function identifier
18                final String funcId = ctx.funcId.getText();
19                final int paramNumber = ctx.formalParams.decls.size();
20                final TypeInformation[] paramTypes =
21                    new TypeInformation[paramNumber];
22                // Get parameters
23                for (int i = 0; i < paramNumber; ++i) {
24                    final DataType paramType =
25                        DataType.getType(ctx.formalParams.decls.get(i)
26                            .type.getText());
27                    if (paramType == DataType.VOID) {
28                        throw new WrongDataTypeException(ctx.start);
29                    }
30                    paramTypes[i] = new TypeInformation(paramType);
31                }
32                // Has a function regarding the signature already been
33                // defined?
34                if (definedFunctionPrototypes.contains(funcId,
35                    paramTypes)) {
36                    throw new AlreadyDefinedFunctionException(ctx.funcId);
37                }
38                definedFunctionPrototypes.add(new
39                    TypeInformation(returnType), funcId, paramTypes);
40                return null;
41            }
42        }.visit(tree);
43        return definedFunctionPrototypes;
44    }
45}
```

```

47     private static void setBuiltInFunctionDefinitions(
        FunctionPrototypeList definedFunctions) {
49         definedFunctions.add(new TypeInformation(DataType.VOID), "print",
            new TypeInformation[] {new TypeInformation(DataType.INT)});
        ...
51         definedFunctions.add(new TypeInformation(DataType.INT), "length",
            new TypeInformation[] {new TypeInformation(DataType.SARRAY)});
53     }
}

```

Code 7: Implementation of `FunctionDefinitionVisitor.java`

Among other things, the built-in functions that a user can call later without importing are also defined here. In contrast to the main visitor, the implementation of `aggregateResult` is omitted. Thus states are omitted whereby the method for collecting the respective functions is pure which contributes to the increase of performance. This is stored in an additional list (see code 8):

```

public class FunctionPrototypeList {
2     /** Contains all function prototypes from the respective program. */
    private final List<FunctionPrototype> functionPrototypes;
4     ...
    public final boolean contains(final String functionId, final
6        TypeInformation[] params) {
        for (FunctionPrototype prototype : functionPrototypes) {
8            // Get parameters of the current function in the list
            final TypeInformation[] functionParameters = prototype
10                .getParams();
            // The function may only exist if the number of parameters and
12            // the function name match
            if (functionParameters.length == params.length &&
14                functionId.equals(prototype.getFunctionId())) {
                if (functionParameters.length == 0 && params.length == 0) {
16                    // There are no parameters available =>
                    // The function signatures are the same
18                    return true;
                }
20                boolean match = true;
                // Look more closely at the individual data types of
22                // the parameters
                for (int i = 0; i < functionParameters.length; ++i) {
24                    if (functionParameters[i].getDataType() != params[i]
                        .getDataType()) {
26                        // Data types do not match =>
                        // function signatures cannot be the same
28                        match = false;
                        break;
30                    }
                }
            }
        }
    }
}

```

```

    }
    32     if (match) {
        return true;
    34     }
    }
    36 }
    return false;
    38 }

    public final void add(final TypeInformation typeInfo, final String
        functionId, final TypeInformation[] params) {
    40         functionPrototypes.add(new FunctionPrototype(typeInfo, functionId,
    42             params));
    44     }
    ...
    46     public final FunctionPrototype get(final String functionId, final int
        parameterNumber) {
    48         for (FunctionPrototype prototype : functionPrototypes) {
            if (prototype.getFunctionId().equals(functionId) &&
    50             prototype.getParamNumber() == parameterNumber) {
                return prototype;
    52             }
        }
    54     return null;
    }
    56 }
```

Code 8: Implementation of FunctionPrototypeList.java

The same principle also applies to structures that can be defined individually. There is also a separate visitor which first determines the names of the structures and maps them to positions. The following code 9 shows this procedure:

```

    public class CustomTypeVisitor {
    2     public static LinkedHashMap<String, CustomType> findTypes(final
        ParseTree tree) {
    4         // Saves the names of the structures and their positions (from top
        // to bottom).
    6         final Map<String, Integer> structIds = new LinkedHashMap<>();

        // Holds the structures with variables and types as well as
        // references.
    8         final LinkedHashMap<String, CustomType> structs =
            new LinkedHashMap<>();

    12         // An anonymous class (first round)
    14         new EBaseVisitor<Void>() {
            /** Position of the custom data type */

```

```

16         int typeId = 0;

18         @Override
19         public Void visitStructDeclaration(StructDeclarationContext
20             ctx) {
21             // The name of the structure must not appear twice
22             if (structIds.get(ctx.structId.getText()) != null) {
23                 throw new AlreadyDeclaredStructException(ctx.structId);
24             } else {
25                 structIds.put(ctx.structId.getText(), typeId++);
26             }
27             return null;
28         }
29     }.visit(tree);

30     // An anonymous class (second round)
31     new EBaseVisitor<Void>() {
32         /** Position of the custom data type */
33         int typeId = 0;

34         @Override
35         public Void visitStructDeclaration(StructDeclarationContext
36             ctx) {
37             // Store the variables types
38             final List<TypeInformation> varTypes = new ArrayList<>();
39             // Maps the variable identifiers to its positions
40             final Map<String, Integer> varIds = new HashMap<>();
41             // Iterate over the variables in the structure
42             for (int i = 0; i < ctx.decls.size(); ++i) {
43                 final String varType = ctx.decls.get(i).type.getText();
44                 // Get Data type object for the desired data type
45                 final DataType type = DataType.getType(varType);
46                 TypeInformation newType;
47                 if (type == DataType.OBJREF) {
48                     final Integer structId = structIds.get(varType);
49                     if (structId == null) {
50                         throw new UndeclaredStructException(ctx.decls
51                             .get(i).type.start);
52                     } else {
53                         // There is a reference => Map the variable type
54                         // to the struct position
55                         newType = new TypeInformation(type, structId);
56                     }
57                 } else {
58                     newType = new TypeInformation(type);
59                 }
60                 varTypes.add(newType);
61                 final String varId = ctx.decls.get(i).varId.getText();

```

```

64         if (!varIds.containsKey(varId)) {
            varIds.put(varId, i);
66         } else {
            throw new AlreadyDeclaredVariableException(ctx.decls
68                 .get(i).varId);
        }
70     }
    structs.put(ctx.structId.getText(), new CustomType(typeId++,
72        varTypes, varIds));
    return null;
74 }
}.visit(tree);
76 return structs;
    }
78 }

```

Code 9: Implementation of CustomTypeVisitor.java

Then, references can also be determined within `visitStructDeclaration`. It is possible that types are defined in types which is why a double traversing occurs. Afterwards, the names of the types as well as the attributes and references are stored in a map. In the last traversing before the main traversing the static variables are determined which is shown in the following code 10:

```

public class StaticVariableVisitor {
2    public static Map<String, TypeInformation> findStaticVariables(
        final ParseTree tree, final LinkedHashMap<String, CustomType>
4        structs) {
        // Saves the names and types (also references) of the static
6        // variables.
        final Map<String, TypeInformation> staticVars = new HashMap<>();
8
        // An anonymous class
10    new EBaseVisitor<Void>() {
        int typeId = 0;
12
        @Override
14    public Void visitProgram(ProgramContext ctx) {
        for (ParseTree child : ctx.children) {
16            if (child instanceof StatementCommandContext) {
                visit(child);
18            }
        }
        return null;
20    };
22
    @Override
24    public Void visitVariableDeclaration(VariableDeclarationContext

```

```

    ctx) {
26     final String varType = ctx.type.getText();
    final DataType dataType = DataType.getType(ctx.type
28         .getText());
    final String varId = ctx.varId.getText();
30     if (staticVars.containsKey(varId)) {
        // A variable must not be declared twice
32         throw new AlreadyDeclaredVariableException(ctx.varId);
    } else if (dataType == DataType.OBJREF) {
34         final CustomType struct = structs.get(varType);
        if (struct == null) {
36             throw new UndeclaredStructException(ctx.start);
        } else {
38             // There is a reference => Map the variable type to
            // the struct position
40             staticVars.put(varId, new TypeInformation(typeId,
                dataType, struct.getId()));
42         }
    } else {
44         // Primitive data type
        staticVars.put(varId, new TypeInformation(typeId,
46             dataType));
    }
48     ++typeId;
    return null;
50 }
    }.visit(tree);
52    return staticVars;
    }
54    ...
}

```

Code 10: Implementation of StaticVariableVisitor.java

If there is a reference to a structure, the respective address including the type is inserted, otherwise only the data type. Later, a decision is made between a global or local scope (for functions) about the variable `isGlobal` which specific code is generated. So if, for example, the construct *struct A { int a; } A a = new A(0);* is present, then `Point 0 {int, int}` and `p : 0` would apply with regard to a debug mode, i.e. `p` refers to `Point`. In the case of further structures, the number would be increased. For example, the numbers are then used later during code generation as indexes for variables.

Due to the increased complexity there is an exception handling. In concrete terms, type and declaration analysis are implemented here in the form of exceptions for which a base class 11 is used:

```

1 public class CompilerException extends RuntimeException {

```

```
3    protected int line ;
5
6    protected int column ;
7
8    public CompilerException(Token token) {
9        line = token.getLine();
10       column = token.getCharPositionInLine();
11    }
12 }
```

Code 11: Implementation of `CompilerException.java`

If a construct of language E is used incorrectly, the row, column and reason are specified within the traversal. For example, there are the following exceptions:

- If a variable was not declared before use
- If a variable has been defined twice with respect to the identifier
- If a function was not defined before use
- If a function has been defined twice
- If a structure was not defined before use
- If a structure has been defined twice
- If a wrong data type was used inside an illegal operation
- If an unknown built-in function was used
- If an unknown imported module was used

Note: The exceptions refer to the specific scope.

In the case of `print(a);` the exception `1:6 <Undeclared variable: <a>;` is thrown into `visitVariableDeclaration` (see chapter 3 on page 55) if the identifier is not in the hash table. The same applies to variables that have already been defined. With regard to functions the signature decides whether a function is duplicated or not. As already mentioned, this check is already carried out in the `FunctionDefinitionVisitor` (see code 7 on page 40). If, for example, a `float get_val() { return 1.0; }` `float get_val() { return 2.0; }` was programmed, the message `2:4 Already defined function: <get_val>;` would appear. The respective body and a correct function call are still checked in the main visitor (see code 3 on page 28). In addition, all operations are checked to see whether the data types are compatible with them. For example, if an attempt is made to call the code `String a = 5.0 + 3;`, a `WrongDataTypeException` is thrown. This procedure can also be transferred to the other application scenarios.

The corresponding derived classes can be found in the appendix on page 75.

2.4 Code generation

During code generation, components of the grammar are transformed into code by required instructions, depending on the respective architecture. Here, *Jasmin*¹² is used as assembler for the JVM where bytecode is generated from assembler-like instructions. This can then be interpreted or executed in the JVM. The instructions are described in ASCII format. The basic structure is as follows (see Code 12):

```
1 .class public E
  .super java/lang/Object
3 ...
  .method public static main([Ljava/lang/String;)V
5     .limit stack 100
     .limit locals 100
7 ...
     return
9 .end method;
```

Code 12: Basic structure of *Jasmin*

Jasmin statements are comments, directives and instructions. A comment begins with a semi-colon and the assembler ignores everything after that to the end of line. Directives like `.super` begin with a period and are executed by the assembler rather than the JVM. An instruction can consists of a label, an operator (also called a mnemonic) and operands. For example, these can be arithmetic or logical. The `.super` construct indicates an inheritance in which the corresponding packages must also be specified. The `[L` command specifies an argument with an array of a certain type (also called the descriptor). The symbol `V` stands for no return (also called Void). The command `.limit` can be used to specify upper limits for e.g. the stack or local variables. In this case, the `return` construct determines the end of the main method. Before this are all instructions, such as outputs or variable declarations which are determined during traversing by the AST.

Altogether, the individual programs written in *E* are processed in a queue and compiled individually as shown in the following code 13:

```
1 public class Main {
    /** Temporary directory for the compiled files */
3     private static Path tempDir;

5     /** Parent directory (path to file for legacy) */
```

¹²Jasmin, <https://cs.au.dk/~mis/d0vs/jvmspec/ref-Java.html>

```
private static File parentDir;

7
/** The namespace of the program you want to compile currently */
9 private static String namespace;

11 /** Holds the programs (including path) to compile. */
public static Queue<String> programs;

13
/** Holds the compiled programs (including path). */
15 public static Queue<String> compiledPrograms;

17 public static void main(String[] args) throws Exception {
    // Path to the main program
19     final String fileName = "e/test/main";
    // Create a temporary directory for programs compiled later
21     tempDir = createTempDir(fileName);
    parentDir = tempDir.toFile();
23     programs = new LinkedList<>();
    // Add the program you want to compile
25     programs.add(fileName);
    compiledPrograms = new LinkedList<>();
27     // Process the programs
    while (!programs.isEmpty()) {
29         final String program = programs.poll();
        compiledPrograms.add(program);
31         // Set the namespace for later references
        namespace = program.replace('/', '_');
33         // The current file to compile
        final File currentFile = new File(parentDir.getPath(),
35             namespace + ".e");
        final CharStream srcCode = CharStreams.fromFileName(program +
37             ".e");
        ...

39         // Separate the main program from the structures
        final String[] compiledCode = compile(srcCode).split("\\*");
41         if (!compiledCode[0].isEmpty()) {
            final ClassFile classFile = new ClassFile();
43             classFile.readJasmin(new StringReader(compiledCode[0]), "",
                false);
45             final Path outputPath = tempDir.resolve(currentFile
                .getAbsolutePath().substring(0, currentFile
47                 .getAbsolutePath().length() - 2) + ".class");
            classFile.write(Files.newOutputStream(outputPath));
49             final ClassFile[] extraFiles = new ClassFile[compiledCode
                .length - 1];
51             // Create class files for the declared structs
            for (int i = 0; i < compiledCode.length - 1; ++i) {
53                 final ClassFile file = new ClassFile();
```

```

        extraFiles[i] = file;
55     file.readJasmin(new StringReader(compiledCode[i + 1]),
        "", false);
57     final Path newPath = tempDir.resolve(file.getClassName()
        + ".class");
59     file.write(Files.newOutputStream(newPath));
    }
61 }
}
63 // Run the compiled program
    final String result = runClass(tempDir, fileName.replace("/", "_")
65     );
    // Delete the created temporary directory
67 deleteTempDir();
}

69 public static String compile(final CharStream sourceCode) {
71     // Control characters are ignored
    ELexer lexer = new ELexer(sourceCode);
73     CommonTokenStream tokens = new CommonTokenStream(lexer);
    EParser parser = new EParser(tokens);
75     // Start rule
    ParseTree tree = parser.program();
77     // Collect all function definitions (without body)
    FunctionPrototypeList definedFunctionPrototypes =
79     FunctionDefinitionVisitor.findFunctionPrototypes(tree);
    // Collect all structs with declared variables and types
81     // (including references)
    LinkedHashMap<String, CustomType> declaredStructs =
83     CustomTypeVisitor.findTypes(tree);
    // Collect all static variables in the main program
85     // (including references to structs)
    Map<String, TypeInformation> declaredStaticVars =
87     StaticVariableVisitor.findStaticVariables(tree,
        declaredStructs);
89     // Create an assembler program for Jasmin based on instructions
    return new EVisitor(definedFunctionPrototypes, declaredStructs,
91     declaredStaticVars, namespace, parentDir).visit(tree);
}

93 ...

    public static String runClass(final Path dir, final String className)
95     throws Exception {
        final Process process =
97     Runtime.getRuntime().exec(new String[] {"java", "-cp", dir
        .toString(), className});
99     try (InputStream input = process.getInputStream()) {
        Scanner scanner = new Scanner(input);
101     if (scanner.useDelimiter("\\A").hasNext()) {

```

```
103         String result = scanner.useDelimiter("\\A").next();
104         scanner.close();
105         return result;
106     }
107     scanner.close();
108     return null;
109 }
}
```

Code 13: Implementation of Main.java

In general, the main procedure is as follows:

1. The main program is added to the queue.
2. As long as the queue is not empty, do the following:
 - a) Get the current file to compile from the queue.
 - b) Convert the file to a namespace (for class names, references, etc.).
 - c) Compile the file in several steps (see figure 1 on page 8).
 - d) If there are structures, they are stored in separate class files.

Since there can also be imports (see `visitIncludes` in code 3 on page 28), these are also processed in the queue. Finally, the compiled code can be executed.

After the described context analysis (see chapter 2.3 on page 27) of the example from the figure 8 on page 27 the following code 14 would be generated:

```
1 .class public e_test_main
2 .super java/lang/Object

4 .method public static main([Ljava/lang/String;)V
5     .limit stack 4
6     .limit locals 1

8     getstatic java/lang/System/out Ljava/io/PrintStream;
9     ldc 3
10    ldc 2
11    ldc 4
12    imul
13    iadd
14    invokevirtual java/io/PrintStream/print(I)V

16    return
.end method
```

Code 14: Generated code of *E*

To produce this code, a `StringBuilder` is used (see `visitProgram` in code 3 on page 28). This procedure saves the use of various objects and thus increases performance. The command `getstatic` places the object behind `System/Out` on the stack. Furthermore, the constants 3, 2 and 4 are placed one after the other on the stack. The command `imul` multiplies the two top elements 4 and 2 and puts the result back on the stack. This is then added to the 3 by `iadd`. This procedure is visualized as follows (see figure 9):

Figure 9: Relation between the operations and stack

Note: If functions or structs are used, the respective parameters respectively attributes are also stored on the stack.

With the command `invokevirtual` the method `print` is called with an integer as argument which outputs the result. If the symbol table is to be extended with regard to variables, there are the commands `istore` and `iload` to store a value in a variable from the stack or to get a value from this position (see code 3 on page 28).

In addition, there are many other constructs such as branches, loops, different operators and so on. The following tables 3, 4 and 5 starting on page 52 show the transformation of various such constructs or examples:

Table 3: Code transformations

Component	Instructions	Transformation
<pre>void mul(int a ,int b) { print(a*b); } mul(5, 3);</pre>	<pre>getstatic iload imul invokevirtual ldc invokestatic</pre>	<pre>.method public static mul(II)V .limit locals 2 .limit stack 3 getstatic java/lang/System/out Ljava/io/PrintStream; iload 0 iload 1 imul invokevirtual java/io/PrintStream/print(I)V return .end method ldc 5 ldc 3 invokestatic e_test_main/mul(II)V</pre>
<pre>int a = 1; if (a) { print(5); } else { print(3); }</pre>	<pre>ldc putstatic getstatic ifne goto</pre>	<pre>ldc 1 putstatic main/v0 I getstatic main/v0 I ifne onTrue1 getstatic java/lang/System/out Ljava/io/PrintStream; ldc 3 goto endIf1 onTrue1: getstatic java/lang/System/out Ljava/io/PrintStream; ldc 5 endIf1:</pre>
<pre>print(0 && 1);</pre>	<pre>ldc ifeq goto invokevirtual</pre>	<pre>getstatic java/lang/System/out Ljava/io/PrintStream; ldc 0 ; jump if a is zero ifeq onAndFalse1 ldc 0 ifeq onAndFalse1 ldc 1 goto endAnd1 onAndFalse1: ldc 0 endAnd1: invokevirtual java/io/PrintStream/print(I)V</pre>

With regard to the operations **and** and **or**, the direct use of the instructions **iand** and **ior** is deliberately waived in order to ensure lazy evaluation. With the disjunction the logic is only reversed in comparison to the conjunction. So that the labels for the jumps are unique, they are uniquely identified by a number.

Table 4: Code transformations 2

Component	Instructions	Transformation
<pre> struct Point { int x; int y; } Point p = new Point(1, 2); p.x = 5; </pre>	<pre> aload invokespecial return new dup putstatic getstatic putfield ldc </pre>	<pre> .class struct_main0 .super java/lang/Object .field public a0 I .field public a1 I .method public <init>()V aload_0 invokespecial java/lang/Object/<init>()V return .end method .class public main .super java/lang/Object .field public static v0 Lstruct_main0; .method public static main([Ljava/lang/String;)V .limit stack 4 .limit locals 1 new struct_main0 dup invokespecial struct_main0/<init>()V putstatic main/v0 Lstruct_main0; getstatic main/v0 Lstruct_main0; ldc 1 putfield struct_main0/a0 I getstatic main/v0 Lstruct_main0; ldc 2 putfield struct_main0/a1 I getstatic main/v0 Lstruct_main0; putstatic main/v0 Lstruct_main0; getstatic main/v0 Lstruct_main0; ldc 5 putfield struct_main0/a0 I return .end method </pre>

A separate class is created for each structure. Attributes are assigned via `.field` and there is a default constructor that is initially loaded. In the main class there is a reference to this structure which is identified by `L`. A structure is created with `new` or the standard constructor is called with `invokespecial`. With `.putfield` values are assigned to the attributes. The suffixes of each variable name result from the position in the symbol table.

Table 5: Code transformations 3

Component	Instructions	Transformation
<pre>int[] a = new int[3]; a[0] = 5; print(a[0]);</pre>	<pre>ldc newarray putstatic getstatic iastore iaload invokevirtual</pre>	<pre>ldc 3 newarray int putstatic main/v0 [I getstatic main/v0 [I ldc 0 ldc 5 iastore getstatic java/lang/System/out Ljava/io/PrintStream; getstatic main/v0 [I ldc 0 iaload invokevirtual java/io/PrintStream/print(I)V</pre>
<pre>int i = 0; while (i < 3) { i = i + 1; }</pre>	<pre>ldc putstatic getstatic if_icmplt goto ifeq iadd</pre>	<pre>ldc 0 putstatic main/v0 I beginLoop1: getstatic main/v0 I ldc 3 if_icmplt onCmpTrue1 ldc 0 goto endCmp1 onCmpTrue1: ldc 1 endCmp1: ifeq endLoop1 getstatic main/v0 I ldc 1 iadd putstatic main/v0 I goto beginLoop1 endLoop1:</pre>
<pre>int i = 2 < 2;</pre>	<pre>ldc if_icmplt goto putstatic</pre>	<pre>ldc 2 ldc 2 if_icmplt onCmpTrue1 ldc 0 goto endCmp1 onCmpTrue1: ldc 1 endCmp1: putstatic main/v0 I</pre>

Overall, these results are aggregated. In code 3 on page 28, the method `visitChildren` can be recognized during traversing in this context. This method is executed on several nodes which is why the method `aggregateResult` is called internally there to aggregate the specific instructions. The relevant operands are also placed on the stack.

A list of more relevant commands with descriptions can be found in the appendix on page 78. Finally, a more complex example can be found in the appendix on page 80.

3 Tests

This chapter presents the tests for the compiler. The development process was *Test Driven Development* (TDD). This process is shown in the following figure 10:

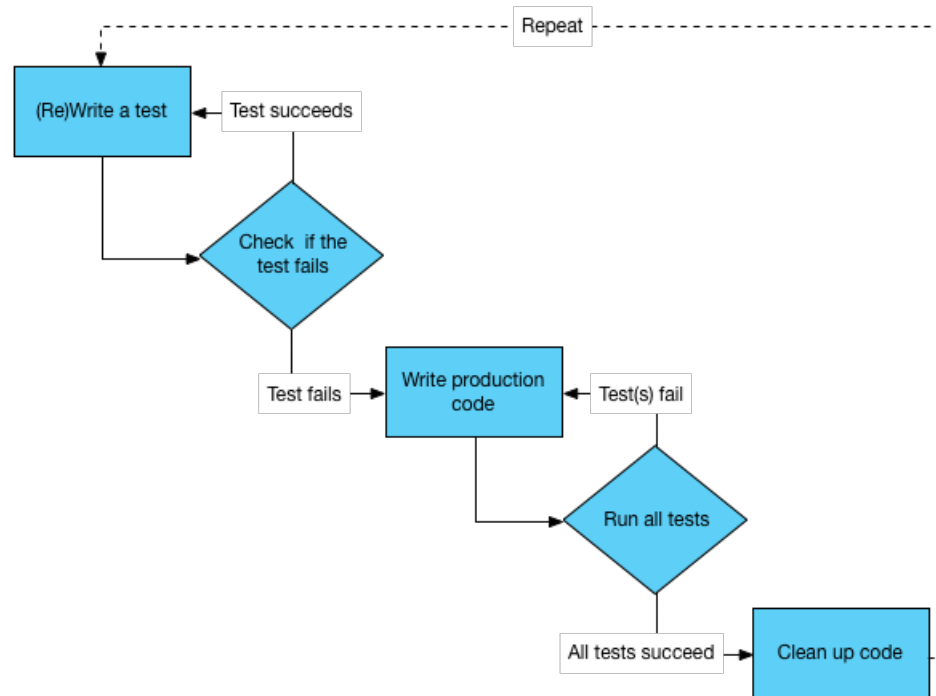

Figure 10: Test Driven Development

Test cases were created as early as possible and derived from desired use cases of the compiler. Furthermore, they specified the preconditions and the behavior of the respective product functions. If the parser did not throw any more mistakes, then the grammar was correct. However, a `NoSuchElementException` indicated that the instruction code was still produced incorrectly. Therefore, the test drivers were developed first whereby methods were partially defined at the beginning.

The unit and integration tests serve to exclude errors of the calculated results. TestNG¹³ was used as test framework. It is inspired by JUnit¹⁴ but is easier to use and offers more functionalities like annotations or a flexible test configuration. The test suite is structured as follows (see code 15):

```

1 public class CompilerTest {
    @BeforeClass
3     public void createTempDir() throws Exception {
        Main.tempDir = Main.createTempDir("compilerTest");
5     }
  
```

¹³TestNG, <https://testng.org/doc/index.html>

¹⁴JUnit, <https://junit.org/junit5/>

```

7  @AfterClass
  public void deleteTempDir() {
9      Main.deleteRecursive(Main.tempDir.toFile());
  }

11

13  @DataProvider
  public Object[][] provideCodeExpectedOutput() {
      return new Object[][] {
15          {"Print a number", "print(1);", "1"},
          {"Print a number with a new line", "println(1);", "1" +
17              System.lineSeparator()},

197    }
}

```

Code 15: Implementation of `CompilerTest.java`

Before execution a temporary folder “compilerTest” is created by the method `createTempDir`. This folder is deleted via `deleteTempDir` or `deleteRecursive`. The test is annotated by `@test` where a data provider `provideCodeExpectedOutput` is registered. This holds the individual code snippets or components of the compiler (see code 2 on page 19) which are tested individually and continuously. The first string represents the description, the second the source code and the third the expected result. Since there are also longer constructs, these are loaded separately from files using the `loadTestCode` method. The individual files are listed in the appendix on page 90. The error messages are also tested which is annotated by the expected exceptions. The current result is determined by the `compileAndRun` method. The corresponding compilation is created in the class `Main` (see code 13 on page 47). An excerpt of the tests can be seen in the figure 11 below:

Figure 11: Unit and integrations tests

Accordingly, it can be recognized that all 83 tests regarding arithmetic operators, outputs, functions, variable declarations, loops, branches, structures etc. have been successful and that the compiler works correctly regarding language *E*. To ensure the code quality, Google Java Format¹⁵ was still used which formats the code. Checkstyle¹⁶ was also used. It can find class design problems, method design problems. It also has the ability to check code layout and formatting issues.

¹⁵Google Java Format, <https://github.com/google/google-java-format>

¹⁶Checkstyle, <https://maven.apache.org/plugins/maven-checkstyle-plugin/>

4 Summary and Conclusion

In this paper the development of an own language *E* or the corresponding platform-independent compiler was described. This concerns both analysis and synthesis (see figure 1 on page 8). The focus was on traversing the AST (see chapter 2.3 on page 27) and code generation (see chapter 2.4 on page 47). Accordingly, the source code is translated into byte code after traversing (to exclude type errors, etc.) and can be executed in the JVM. The aim was to be able to describe a lot with as few expressions as possible and to demonstrate different constructs. In addition, conventional language properties should be removed until a Turing machine-like language remains. Various unit and integration tests should ensure the quality of the compiler.

The language *E* supports different data types (see chapter 2.1 on page 12) like booleans, integers, floating point numbers, strings, arrays and objects as well as different commands (see chapter 2.2 on page 18). This includes functions, structures and different statements like branches, loops, variables and inline assembler. These are separated so that global visibility is also possible. Thus e.g. function definitions or structure declarations can stand below their use. Through the use of while loops, the language is even Turing complete, thus providing universal programmability. The system and a universal Turing machine can thus emulate each other or each program part can be converted into a different language and vice versa. Since the libraries provided are still restrictive, it is possible to program different routines with inline assembly, e.g. in dealing with file systems (see appendix on page 92).

TDD was used as the development process (see figure 10 on page 55). Various tests (see chapter 3 on page 55) check the correctness of the provided constructs. This refers to the direct application as well as the interaction between different components. For example, branches can also be used in loops. Furthermore, a static code analysis was performed to find possible errors such as unreachable code. This procedure was repeated until all tests were successful (see figure 11 on page 60).

Finally, it should be said that optimized code is produced in relation to the realized language constructs (see appendix from page 80) and all known possible programming errors are found by the lexer, parser and context analysis. Also a possible conversion to interpretation would be possible. It would be conceivable, for example, that a generic data type instead of a string would be used as the return value of the visitor methods (see code 3 on page 28). Thus, individual data types can be set and checked. Output then takes place, for example, directly in Java. Also a flexible further development of the language constructs is given by the ease of maintenance.

```

Code 17: Generation of ELexer.java

Deterministic context-free language classes

Recursive descent parser (top-down)		Shift reduce parser (bottom-up)	
$LL(k)$	Predicts the next production using k tokens (taking the stack contents into account). The left context must therefore be noted.	$LR(k)$	Detects syntax errors as soon as possible and can parse all deterministic context-free languages. $LR(1)$ is canonical but relatively large parser tables are created.
$SLL(k)$	Indicates a subset of $LL(k)$ where the left context does not have to be kept.	$SLR(k)$	Creates simple parser tables and is relatively easy to implement. However, not all deterministic grammars can be handled with it. It does not have to scan all lookahead reductions.
		$LALR(k)$	The complexity lies between LR and SLR . It therefore has a similar number of states to SLR but recognizes more languages. It tries to combine states if goto tables and lookaheads are compatible. Conflicts are recognized by rules.
		$GLR(k)$	Detects ambiguous grammars through rules and can be combined with $LALR$.

Generation of the parser

```

10    }
12 }
```

Code 27: Implementation of UnknownModuleException.java

Jasmin instructions

Table 8: Relevant instructions of Jasmin

Instruction	Opcode	Description
<code>dup</code>	0x59	This pops the top single-word value off the operand stack and then pushes that value twice.
<code>f2i</code>	0x8B	Pops a single precision float off of the stack, casts it to a 32-bit integer and pushes the integer value back onto the stack.
<code>getstatic</code>	0xB2	Pops a reference to an object from the stack, retrieves the value of the static field (also known as a class field) identified by a field specification from the reference and pushes the one-word or two-word value onto the operand stack.
<code>goto</code>	0xA7	Causes execution to branch to the instruction at the address ($pc + \text{branchoffset}$), where pc is the address of the <code>goto</code> opcode in the bytecode and branchoffset is a 16-bit signed integer parameter that immediately follows the <code>goto</code> opcode in the bytecode.
<code>iadd</code>	0x60	Pops two integers from the stack, adds them and pushes the integer result back onto the stack.
<code>idiv</code>	0x6C	Pops the top two integers from the operand stack and divides the second-from top integer by the top integer. The quotient result is truncated to the nearest integer and placed on the stack.
<code>ifeq</code>	0x99	Pops the top integer off the operand stack. If the integer equals zero, execution branches to the address ($pc + \text{branchoffset}$).
<code>ifne</code>	0x9A	Pops the top integer off the operand stack. If the integer does not equal zero, execution branches to the address ($pc + \text{branchoffset}$).
<code>if_icmplt</code>	0xA1	Pops the top two ints off the stack and compares them.
<code>iload</code>	0x15	Loads a value from the table regarding variables at a desired position onto the stack.
<code>imul</code>	0x68	Pops the top two integers from the operand stack, multiplies them and pushes the result back onto the stack.
<code>invokespecial</code>	0xB7	Is used in certain special cases to invoke a method.
<code>invokestatic</code>	0xB8	Calls a static method (also known as a class method).

Table 9: Relevant instructions of Jasmin 2

Instruction	Opcode	Description
<code>invokevirtual</code>	0xB6	Dispatches a Java method. It is used in Java to invoke all methods except interface methods.
<code>irem</code>	0x70	Pops two integers from the operand stack, divides <i>value2</i> by <i>value1</i> , computes the remainder and pushes the integer remainder back onto the stack.
<code>ireturn</code>	0xAC	Pops an integer from the top of the stack and pushes it onto the operand stack of the invoker.
<code>ishl</code>	0x78	Pops two integers off the stack. Shifts <i>value2</i> left by the amount indicated in the five low bits of <i>value1</i> . The integer result is then pushed back onto the stack.
<code>ishr</code>	0x7A	Pops two integers off the stack. Shifts <i>value1</i> right by the amount indicated in the five low bits of <i>value2</i> . The integer result is then pushed back onto the stack. <i>value1</i> is shifted arithmetically (preserving the sign extension).
<code>istore</code>	0x36	Gets the topmost integer from the stack and places it in the table regarding the variables.
<code>isub</code>	0x64	Pops two integers from the stack, subtracts the top one from the second one and pushes the result back onto the stack.
<code>ixor</code>	0x82	Pops two integers off the operand stack. Computes the bitwise exclusive or of <i>value1</i> and <i>value2</i> . The integer result replaces <i>value1</i> and <i>value2</i> on the stack.
<code>i2f</code>	0x86	Pops an integer off the operand stack, casts it into a single-precision float and pushes the float back onto the stack.
<code>ldc</code>	0x12	Loads a constant value onto the stack.
<code>new</code>	0xBB	Determines the size in bytes of instances of the given class and allocates memory for the new instance from the garbage collected heap.
<code>newarray</code>	0xBC	Pops a positive integer off the stack and constructs an array for holding <i>n</i> elements of the given type.
<code>putstatic</code>	0xB3	Sets the value of the static field identified by a field specification to the single or double word value on the operand stack.

Note: The *value2* is always below *value1*. There are prefixes for several data types for different operators. For example, there is `fadd` for the addition of floating point numbers. There are also special Jasmin commands like `.field` to add an attribute to a class.

Example of an E program

```
1 // Different library imports
2 use(e.std.math)
3
4 /**
5  * A point in a two-dimensional space
6  *
7  * @author Rune Krauss
8  */
9 struct Point1 {
10     int x;
11     int y;
12 }
13
14 /**
15  * One more point in a two-dimensional space
16  *
17  * @author Rune Krauss
18  */
19 struct Point2 {
20     float x;
21     float y;
22 }
23
24 /**
25  * Finds the square root of an integer.
26  *
27  * @param x Integer
28  * @return Square root
29  */
30 int sqrt(int x) {
31     int result;
32     // Illegal
33     if (x < 0) {
34         result = -1;
35     }
36     // Base cases
37     if (x == 0 || x == 1) {
38         result = x;
39     } else {
40         int temp = 1;
41         int i = 1;
42         /*
43          * Starting from 1, try all numbers until
44          * i*i is greater than or equal to x
45          */
46         while (temp <= x) {
```

```

        i = i + 1;
48      temp = i * i;
    }
50    result = i - 1;
  }
52  return result;
}

54
/**
56  * Calculates the distance between two points.
  *
58  * @param x1 X value of the first point

    asm {  
3        "  
        ldc 5.1  
5        ldc 0.4  
        fadd  
7        "  
    }  
9    setTopOfStack "float";  
    return topOfStack;  
11 }  
  print(number());
```

Code 44: Implementation of inline_asm.e

```
// Prints 5  
2 print(5);
```

Code 45: Implementation of line_comment.e

```
/*  
2  * Returns an id.  
  */  
4 int id(int x) {  
    return x;  
6 }  
  print(5);
```

Code 46: Implementation of multiline_comment.e

```
1 /**  
  * Returns an id.  
3  *  
  * @param x Number  
5  * @return Id  
  */  
7 int id(int x) {  
    return x;  
9 }  
  print(5);
```

Code 47: Implementation of special_comment.e
